Pennsylvania. The word can bring to mind visions of cities, mountains, and forests; lakes and rivers; fertile farmlands and rugged back country. Perhaps, too, thoughts of the coal mines and steel mills that helped forge the state’s role as a leader in building America’s industrious might. All of these things help define Pennsylvania and make it unique among the fifty states, and all are related to geology.

The dictionary lists two definitions of “geology.” Geology is a science that deals with the study of the earth and its history. Geology is also a name given to the natural features of our planet. In this booklet, we will use the word in both senses. We will describe the natural features that are found in Pennsylvania, and we will see how the science of geology helps us to understand how those features came to be.

Just as you might use a dictionary for reference to check the spelling and definitions of words, there are tools that geologists use for reference. One of these tools, a geologic time chart, is shown on the back cover of this booklet. All scientific evidence indicates that the earth is about 4.5 billion years old. Geologists separate this time into the divisions shown on the chart and conveniently refer to the time intervals by name (for example, “Devonian Period”) rather than by the range of years represented. This is similar to the way in which we group days into months and years rather than counting each day from the beginning of our lives.
The other tool is a special type of map called a geologic map. Most areas of Pennsylvania are covered by a few inches to many feet of soil. The solid rock that is found below the soil is called bedrock. A geologic map shows the age and type of bedrock that is closest to the surface. In the center of this booklet is a simplified geologic map of Pennsylvania that shows the ages of bedrock. It also shows the state’s physiographic provinces, which are areas within which landscapes and rocks are somewhat similar.

KEEPERS OF THE GEOLOGIC RECORD

Imagine a winter’s morning. The ground has a fresh white coating. No one has to tell you that snow fell overnight. You see tracks in the snow. Paw prints. A cat must have walked past after the snow stopped falling. Nearby are a person’s footprints. An early riser, no doubt, but not as early as the cat. You know this because where the paths of the person and the cat crossed the cat’s paw prints were destroyed by the person’s footsteps.

You dig through the snow and find a layer of old, dirty snow. You remember the snowfall of last week. You keep digging until you find some matted stems and leaves. This is the spot where, last spring, you planted a garden. The stems and leaves remind you of the flowers that bloomed on this spot.

The work of a geologist is much like this experience. Nature records many things in a language that we can read with a little practice. This record of events is called the geologic record. Each layer of rock is a keeper of the geologic record and has its own story to tell about how it formed and what plants and animals were present when it was forming. It can even tell us what geologic forces have operated in the area where it is found.

There are three major types of rocks, which are defined by the way in which they formed. In Pennsylvania, the type that we find most commonly is sedimentary rock. This includes rocks that have formed from sand, gravel, or clay that has become naturally cemented together. The appearance of the rocks can reveal something about how they formed. Sandstone consists of layers of sand that have hard-
Shale forms from layers of clay or mud. Rocks such as sandstone and shale are called clastic rocks. Other sedimentary rocks include carbonate rocks, such as limestone and dolomite, which are formed of calcium and magnesium carbonates produced by organisms in the sea. Some carbonates form huge mounds called reefs. Reefs that are hundreds of millions of years old can be found in the geologic record. Some reefs are forming today; an example is the Great Barrier Reef of Australia.

The accumulation of sediments is similar to a snowfall. The tracks in the snow and the remains of last summer’s garden can be compared to the signs of past life that are sometimes found in rocks. Some are indirect signs, such as the footprints of animals that walked by when the sediments were accumulating. Others are more direct, such as the remains of the animals or plants themselves. Any sign of past life is called a fossil.

Plant and animal species very slowly evolve, or change, through time because the ones that are better adapted to their environment are more likely to survive and reproduce. If we compare fossils to each other and to living plants and animals, we can usually determine the relative ages of the rocks in which they are found and the conditions under which they formed.

Finding the dead plants beneath the snow told us that at some time in the past, conditions were suitable for them to have grown. The fact that the plants died suggests that conditions changed rapidly as
winter approached. The absence of living plants suggests, but does not prove, that those species of plants cannot live in the cold, snowy environment. But we do have proof that cats and humans can live under such conditions. We know this because we found their footprints in the snow.

Metamorphic rocks, another of the major rock types, include the very old rocks in Pennsylvania—the ones that have seen the most history and that have the most to tell us. They can be found near the surface in the southeastern part of the state and at great depth anywhere in Pennsylvania. They are rocks that have been changed from their original forms, usually as a result of intense heat, pressure, or both. Gneiss, schist, and slate are examples of metamorphic rocks.

Igneous rocks, the third major type of rock, include rocks formed from red-hot material, called lava, that erupted from volcanoes, sometimes with explosive force. Many other igneous rocks formed quietly from magma (molten rock) that intruded existing bedrock and cooled slowly underground without ever reaching the surface. Examples include granite and diabase. Igneous rocks are found mainly in southeastern Pennsylvania, and many of the metamorphic rocks in that area were also once igneous.
A DIM, DISTANT PAST

Before exploring the geologic record, let us travel back in time to a dim, distant past that even the geologic record does not reveal. The origin of Pennsylvania is tied, as it must be, to the origins of much larger things. Pennsylvania is a part of the North American continent on our planet Earth, which together with the sun, other planets, and smaller celestial bodies make up the solar system. The sun, which dominates the solar system because of its great size, is a star. It appears so different from the stars of the night sky because it is very close to us—only 93 million miles away. The next nearest star, Alpha Centauri, is 25 trillion miles away! Light from Alpha Centauri, traveling at 186,000
miles per second, takes 4.3 years to reach us. Light from the sun reaches us in about 8 minutes. The sun and Alpha Centauri are two of the 100 billion or more stars that form a huge spiral called the Milky Way galaxy. Our galaxy is so unimaginably enormous that a beam of light takes 100,000 years to travel across it. The universe is believed to contain a billion or more galaxies like the Milky Way!

Observations show that the universe is expanding. This, combined with other data, suggests that the universe came into existence 12 to 15 billion years ago in an event called the Big Bang. At that instant, all matter and energy that exist in the universe began expanding outward from a single point, an expansion that continues today.

As matter spread out, hydrogen, the most abundant and simplest of the chemical elements, collected to form great rotating clouds. Within these clouds, which were to become the galaxies, smaller swirling clouds formed. Gravity caused the centers of these smaller clouds to become so dense that a reaction called nuclear fusion began to take place. Fusion converts hydrogen into the heavier element helium, giving off heat and light. These smaller clouds became the stars.

Billions of years passed between the Big Bang and the birth of our sun 4.5 billion years ago. During that time, many other stars were born and died. In many aging stars, some helium is converted into still heavier elements. At the end of their lives, some of the stars explode, sending their elements hurtling through space. Such common elements as oxygen, carbon, nitrogen, silicon, iron, calcium, and potassium were manufactured in stars in this way. Because our sun formed after so many other stars had gone through this process, heavy elements were present in the cloud from which it formed. As the sun was forming, smaller condensations of matter formed around it. These smaller condensations became the planets, and the third one out from the sun became Earth.

When we study the geologic record to learn about the history of the earth, we find that the farther back we look, the more difficult it is to interpret the clues. This is because the earth is dynamic, having a surface that is always changing. These changes record events, but
they also destroy evidence of earlier events, just as the person walking in the snow left footprints but destroyed some of the cat’s paw prints. If enough people had walked by, their footprints might have destroyed all evidence that the cat had ever been there. If the day had become warm enough, the snow would have melted, and there would have been no evidence that anything had happened.

Probably the best record of what the earth might have been like in its earliest days can be found by studying less-active bodies in the solar system, where a record of events that took place long ago would more likely be preserved. Our moon is such a place. It is now geologically inactive. Its oldest areas have a surface that is dominated by craters of all sizes, suggesting that it was once heavily bombarded by meteorites and comets. Relatively newer surfaces, covered by large lava flows, show much less cratering. It is probable that the earth, too, was bombarded by meteorites and comets in its earliest days and later underwent a period of intense volcanic activity. Both comets and volcanoes can release gases and water vapor. On the moon, the gases and vapor would have escaped the weak gravity field and drifted into space. On the earth, they remained to form the atmosphere and oceans. The moon is now quiet, but the earth continues to change. Even the continents move! The great fun of geology is discovering the history of our planet by looking at the rocks that are all around us. They hold the clues to understanding the changes that have formed the earth as we know it today, and to understanding the changes that are still taking place.
THE PRE-ARCHEAN, ARCHEAN, AND PROTEROZOIC

During pre-Archean time, which extended from at least 4.5 to 4 billion years ago, the earth became zoned into contrasting parts, which consisted of a liquid, heavy-metal core, a mantle of heavy, silica-deficient, partially molten rock, and a thin crust of silica-rich rock that floats on the mantle. Geologists believe that bombardment of the surface by meteorites and comets caused the development of ocean basins and continents by 3.7 billion years ago. However, because this happened so long ago, we do not know where these ocean basins and continents were located.

Each impact created a crater and contributed to increasing the temperature within the earth. The increased temperature caused partial melting of the mantle and the generation of basaltic magma, which is molten rock that is low in silica. Because magma, like most substances, becomes less dense when it is heated, the heated magma rose to the surface in various places. As it did so, cooler, denser substances sank lower in the mantle to replace it. This cycle of exchange of hot and cool materials formed convection currents that circulate through the mantle to this day. These convection currents affect the thin crust that rides atop the mantle, causing uplift and movement of sections of the crust.

In addition to craters and heat, the impacts created small areas of land composed of igneous rock. These areas, called microplates, probably formed more or less uniformly around the earth, but the convection currents in the mantle rearranged them, clearing them away from areas where the currents were rising and diverging, and concentrating them in areas where the currents were converging and descending.

About 2.5 billion years ago, at the beginning of Proterozoic time, the steady bombardment gradually decreased. However, the convection
currents continued to move the microplates and cause them to collide. When two microplates collided, they accreted, or combined, to make a larger plate. Eventually the main masses, or cratons, of the continents were formed in this way. Meanwhile, erosion began wearing away the surfaces of the land areas. The eroded sediments were transported by running water and deposited both within the land areas and at their margins. When a collision occurred, rocks and sediments at the margin of each microplate were deformed. In some cases, rocks from one colliding plate were forced down under the other plate in a process called subduction. The heat and pressure generated by such a collision was enough to alter the mineralogy of the marginal rocks and sediments to form new, metamorphic rocks.

The Laurentian continental crustal block, which forms the craton of North America, is made up of many microplates, which were accreted during the period from about 2.5 to 1.0 billion years ago. The Laurentian block was once part of an even larger landmass, called Rodinia, that included all or most of the then-existing land.

Geologists believe that Pennsylvania is underlain everywhere by rocks that belong to one of the last accretions to the Laurentian block, known as Grenville rocks. The Grenville rocks are metamorphic rocks composed mainly of gneiss, a rock that has distinctive layering and mineralogy. Some of these rocks can be seen at the surface in southeastern Pennsylvania, but in most of the state, they are deeply buried under younger rocks and commonly referred to as basement rocks. Note that bedrock units are usually named for places where they have been identified and described in detail. The Grenville rocks are named for a township in Ontario, Canada.

About 725 million years ago, the convection currents of the mantle placed stress upon various parts of Rodinia and caused it to
break up into three large blocks: Laurentia, Baltica, and Siberia. This process, called rifting, created elongate basins parallel to the present eastern margin of North America. Sediments eroded from land to the west were carried by rivers to these basins and deposited in them. In addition to the eroded sediments, much of the material that filled these basins came from volcanoes and intrusions of magma. A second episode of rifting began about 570 million years ago, creating an ocean known as Iapetus to the east of North America.

During the Archean, life first arose as simple forms, such as bacteria. More complex forms of life, such as blue-green algae, single-celled animals, and eventually multicelled organisms, arose during the Proterozoic. There is uncertainty about how this life originated. Studies have shown that comets and some meteorites contain complex organic molecules that, under the right conditions, could be the building blocks of primitive organisms. One possibility is that life was carried to our planet in this form by one or more of the many comets or meteorites that impacted the earth during its early years. Geologic evidence shows that life has existed on earth for approximately 3.9 billion years. The early algae were critical to the further evolution of life because they were able to take carbon dioxide (CO$_2$) out of the atmosphere and release oxygen (O$_2$) into the atmosphere. The atmosphere at that time contained much more carbon dioxide than it does now and was very suitable for the algae, but inhospitable to other forms of life. As the amount of oxygen increased, new forms of life evolved, and by the end of the Proterozoic, about 542 million years ago, multicellular life was widespread and included such forms as mounds of algae (called stromatolites), jellyfish, and worms that lived in the sea.
At the start of the Cambrian Period, water from the Iapetus Ocean transgressed, or spread inland, across North America, covering the Proterozoic rocks of Pennsylvania with relatively shallow water and creating unique environments for the deposition of sediments and the development of life.

Much of North America remained above the sea and was eroded by running water. The eroded sediments were carried by rivers to the ocean. Sand was deposited near the shore while mud was deposited farther offshore. Carbonates were deposited offshore in warm areas that received little or no clastic sediments. As the shoreline moved west, the carbonate shelf remained under shallow water much of the time.

The position and orientation of North America have changed throughout its history because of the action of the convection currents in the mantle. During the Cambrian Period, North America was on the equator, so the climate was warm. The continent was oriented so that the present east coast faced south. For simplicity, geographic directions in this book are relative to North America’s present orientation.

About 488 million years ago, the Cambrian Period ended and the Ordovician Period, which lasted approximately 44 million years,
began. In Pennsylvania, the transition was peaceful with continued de-
position. However, the Ordovician became a time of dramatic changes.

In the Early Ordovician, east of North America and across an
unknown distance of ocean, the convection currents in the mantle
are believed to have changed direction. Subduction began where the
new currents met and new land in the form of a magmatic or vol-
canic arc was created. During subduction, part of the crust is pulled
down toward the mantle and heated. The heating causes a buildup of
pressure, which can lead to explosive volcanic activity. As a present-
day example, volcanoes of the Cascade Range in Washington and
Oregon exist because of subduc-
tion of Pacific Ocean crust under
North America. Ash spewed
by the volcanoes of the Ordo-
vician magmatic arc east of
North America fell into the
water covering North America.
Some of that ash was preserved
and can be seen today in car-
bonate rocks that are exposed
in central and eastern Pennsyl-
avnia.

During the Middle Ordovician, convection currents caused the
volcanic arc to move toward North America. During the Late Ordovi-
cian, material from both the arc and the floor of the Iapetus Ocean
was thrust onto the North American plate margin in an event called
the Taconic orogeny. Mountains formed where material was thrust
onto the continental plate. At the same time, the weight of the ma-
terial thrust onto the plate margin caused it to subside. An elongate
basin, called the Appalachian basin, formed west of the mountains.
The basin, which extended from Newfoundland to Alabama, filled
with marine water and existed for the next 200 million years. This
example of plate tectonics, the movement of various pieces of land,
is comparable to a present-day situation in the South Pacific Ocean,
where the volcanic islands of Indonesia are moving toward Australia.

The mountains formed by the Taconic orogeny lay to the east of
Pennsylvania. Sediments eroded from these mountains were carried
westward by rivers and deposited in the water-filled Appalachian basin. Initially the sediments were mainly silt and clay, but by the end of the Ordovician, sand and gravel were being carried to the Appalachian basin. These clastic sediments brought an end to the long, uninterrupted time of carbonate deposition.

By the beginning of the Cambrian Period, the amount of oxygen in the atmosphere and shallow seas had accumulated to a high enough level that animal life was abundant. Some of the animals had hard shells that offered protection from predators. The animals, which were generally small, flourished, evolved, and became widespread during the Cambrian and Ordovician Periods. Trilobites, multilegged animals that crawled about scavenging for food at the bottom of the sea, were abundant, as were brachiopods, shelled bottom dwellers. They were joined in the Ordovician seas by molluscs, bryozoa, corals, and graptolites. Graptolites are thought to have been floating animals that lived attached to each other in colonies.

The change from deposition of carbonates to deposition of clastic sediments caused by the Taconic orogeny brought death to many animals because it destroyed their dwelling places. However, tragedy for some was opportunity for others as newly created environments were occupied by newly evolved animals. Most of the marine ecosystems that exist today were established during the Ordovician Period.
THE SILURIAN PERIOD

During the Silurian Period, which began about 444 million years ago and lasted for about 28 million years, the position of North America relative to the equator remained nearly the same. However, the orientation of the continent began a very gradual change that would eventually bring it to its present orientation.

The Taconic mountains formed during the Ordovician Period continued to be a source of large quantities of sediments during the first half of the Silurian Period in Pennsylvania. Sand and gravel composed mainly of quartz were carried by streams and deposited on a surface called an alluvial plain in the eastern part of the state. Additional quartz sand was carried farther west into the marine basin, where it was deposited on beaches or just offshore. Today, millions of years later, rock created by the cementation of this sand forms the crests of some of the long, linear ridges in the Ridge and Valley province (see centerfold map). This sandstone, called the Tuscarora Formation, is very hard and resistant to erosion. Because it is more resistant to erosion than rocks immediately adjacent to it, the Tuscarora forms the highest parts of some mountains, including Blue Mountain and Tuscarora Mountain.

Mud was deposited farther west in deeper marine waters. Carbonate deposition, similar to that of the Ordovician Period, occurred even farther west, beyond the boundaries of Pennsylvania. Very intense chemical weathering of the rocks in the mountains released large amounts of iron. This iron was carried in solution into the marine basin and precipitated there. Many of the resulting iron deposits were mined in Pennsylvania throughout most of the 1800’s. They provided America with a valuable resource that greatly aided the development of our nation.

Erosion gradually lowered the height of the mountains formed by the Taconic orogeny, and eventually, the remnants of the mountains ceased to be a significant source of clastic sediments. Carbonate deposition dominated the second half of the Silurian Period, and limestone and dolomite formed in much of the Appalachian basin. At the same time, a shallow basin having very limited circulation of water with the open sea formed in the northwestern part of Pennsylvania and in adjacent New York and Ohio. The warm temperatures associated with the basin’s nearness to the equator caused the water to
evaporate quickly. As evaporation took place, the remaining water became supersaturated, meaning it contained more material than could remain in solution. As a result, minerals such as halite (common table salt) and gypsum crystallized out of the water in large quantities. These deposits, known as evaporites, are today buried beneath younger rocks and are extensively mined in New York and Ohio.

Life during the Silurian Period flourished, and many new species appeared. Corals became very abundant and began to form reefs in the carbonate areas. Corals deposit a very thin layer of lime (calcium carbonate) on their skeletons every day. The width of these layers, called growth rings, changes annually. Some geologists have used coral growth rings to estimate the lengths of years and days. They found that during the Late Silurian, a year consisted of approximately 407 21.5-hour days. If we compare that with today’s 24-hour day, we can conclude that the rate of the earth’s rotation on its axis is slowing. This slowing is caused by friction generated by the continual movement of water across the seafloor in response to the gravitational pull of the moon and sun. We can observe this movement as the twice-daily rise and fall of ocean tides.

Two aspects of life in the Silurian Period are of particular importance to us today. The first is the evolution of fish. The earliest fish had no jaws, only an open mouth. In the Silurian Period, fish developed jaws, their bony plates were reduced to scales, and the strength
of their fins was increased. Their continuing evolution allowed them to move into new environments, such as tidal and freshwater ponds. The second important aspect of Silurian life is the development of plant life on the land. A few plants having roots to obtain water and nourishment from the soil appeared during the Silurian. Once plant life was established on the land, new environments and a food supply were available for evolving animal life.

THE DEVONIAN PERIOD

The transition into the Devonian Period about 416 million years ago was quiet in Pennsylvania, and carbonate deposition continued for a few million years. However, by the end of the Devonian, about 57 million years later, dramatic changes had occurred.

Two landmasses, one called Avalonia and the other Europe, moved toward and eventually collided with North America in an event known as the Acadian orogeny. This collision affected the whole length of the Appalachian basin, but not all at the same time. The collision occurred first near Newfoundland and much later in the area of Pennsylvania. The orogeny created a new mountain range, the Acadian mountains, just east of Pennsylvania.

As the collision occurred and the Acadian mountains rose above sea level, sediments eroded from the mountains were transported by rivers to the Appalachian basin. The first sediments to be deposited can be seen today as black and gray shales and siltstones that extend from eastern Pennsylvania to western Ohio. Erosion of the mountains continued and coarse-grained clastic sediments were carried into the Appalachian basin.

As more and more sediments poured into the basin, the part of the basin nearest the mountains was filled to sea level, and deposition began to occur above sea level on an alluvial plain. The whole process of basin filling involved deposition of coarse-grained sediments on the alluvial plain, movement and deposition of fine-grained sediments by marine currents near the shore, and deposition from suspension of very fine-grained sediments in deeper water farther west. The weight of the sediments being continually deposited in the basin depressed
the crust into the underlying denser mantle. This caused the basin to subside, thus making room for the deposition of still more sediments.

As the shoreline was pushed westward by the growth of the alluvial plain, sediments earlier deposited in marine environments were overlain by sediments deposited in nonmarine environments. This vertical stacking of sediments that were deposited in different and formerly adjacent environments is very common in rock sequences, and its recognition in clastic, layered rocks is very important in understanding the sequence of events recorded in the geologic record. It is also important in the exploration for mineral deposits and gas and oil accumulations.

The Devonian streams in Pennsylvania were of two different types, braided and meandering. Each type deposited distinctive and different sediments. The braided streams had many interconnected channels. These streams deposited mainly sand and some gravel.

The meandering streams had a single channel that wandered in a curved path. They deposited sand and gravel within the channel and sand, silt, and clay on the adjacent floodplain during periods of flood. As basin subsidence occurred and meandering continued, the
channel moved across areas that were formerly floodplains, and new floodplains formed above former channels. The repetition of this process resulted in cycles of deposition that can be seen in the sedimentary rocks today.

Continued erosion of the Acadian mountains produced abundant sediments throughout the remainder of the Devonian Period, and the eastern shoreline of the Appalachian basin was pushed almost to the Ohio border. Many of the sediments that were deposited on the alluvial plain are seen today as red clastic rock. The redness is derived from iron oxide, which forms part of the cement in the rock. This redness indicates that deposition occurred above sea level and that the climate was seasonally dry, thus allowing oxidation of any iron in the sediments.

The alluvial plain was also seasonally wet. From the presence of fossils, we know that, at times, the surface was covered by abundant vegetation. Animal life was plentiful, not only in the seas, but also on the land. During the Late Devonian, some fish evolved into amphibians, animals that breathe through gills in infancy and use lungs to breathe air in adulthood. Amphibians were able to leave the ocean and inhabit the land. Many insects and other arthropods were abundant in the forested areas. In a real sense, the land had become alive.
THE MISSISSIPPIAN AND PENNSYLVANIAN PERIODS: CARBONIFEROUS TIME

The 60 million years of Carboniferous time, which started about 359 million years ago, are significant for two reasons. First, it was during this time that the vast quantity of coal in Pennsylvania was formed. Second, it was the last time that marine waters of the Appalachian basin covered any part of Pennsylvania. The name “Carboniferous” is used to refer to two periods, the Mississippian (older) and the Pennsylvanian (younger).

Deposition on the earlier formed alluvial plain continued as the Mississippian Period began, but the color of the resulting rocks is gray in contrast to the red Devonian rocks below. This could be because the climate had more rainfall and the seasons were less distinct. The amount of sediments being carried to the basin declined, and the eastern shoreline of the basin moved eastward across part of Pennsylvania. During the latter part of the Mississippian Period, the fine-grained sediments were turned red by oxidation of iron, perhaps because of a return to a seasonal climate. Carbonates were deposited in the marine waters of western Pennsylvania, which was probably located about 10 degrees south of the equator.

By the end of the Mississippian Period, marine waters had advanced across the southwestern part of the state toward the northeast and into the Williamsport area. The northwestern part of the state was above sea level and was being eroded. Renewed uplift in the Acadian mountains east of Pennsylvania, possibly caused by a minor collision with an unknown landmass, resulted in coarser grained sediments being brought into the Appalachian basin during the Pennsylvanian Period. The sediments were deposited by rivers that meandered across a flat alluvial plain.

In the western part of the state during the Pennsylvanian Period, the area of the alluvial plain near the shoreline was covered by large swamps and lush fern and tree forests. The vegetation was abundant because Pennsylvania was only 5 to 10 degrees south of the equator and had a warm, moist, tropical climate. The plants, which primarily included a large, scaly-barked tree called lycopsid, as well as ferns and tree ferns, produced large quantities of leaves, twigs, branches, and
trunks that fell into the swamps. The fallen parts were protected from oxidation by the water and thus did not rot. This continuous supply of vegetation gradually accumulated as thick masses of wood debris called peat.

These swampy areas often received little or no sediments from the sluggish rivers. Basin subsidence, however, is a regional phenomenon and continued because of sedimentation elsewhere. The swampy areas that did not receive sediments were thus periodically drowned as subsidence continued, sea level rose, and the shoreline moved gradually eastward.

The process of subsidence and shoreline migration was very slow, and new swamps formed continuously adjacent to the sea. Once an area was covered by water, a nearby river would start supplying sediments that would bury it. The shoreline thus moved westward as the alluvial plain extended itself over the area. The heat and pressure caused by the weight of the overlying sediments compacted the peat and forced out some of the more easily vaporized compounds. This process concentrated the carbon and eventually turned the peat into coal. The greater the pressure, the more volatile compounds that were forced out, making the coal richer in carbon, the chief element in coal that burns.
The shoreline moved back and forth across the low, flat alluvial plain several times during the Pennsylvanian Period. It advanced as far eastward as Wilkes-Barre about 310 million years ago. By the end of the Pennsylvanian Period, the Appalachian Sea was completely gone from the state. Sediment deposition on the alluvial plain and the accumulation of wood in the swamps continued into the Permian Period.

Eastern Pennsylvania was far removed from the sea most of the time, but swamps were equally as common in areas adjacent to the rivers, and vast quantities of peat accumulated there, also. Periodic increases in the amount of sediments being brought to an area by a river buried the swamps. When the sediment supply decreased or the river shifted its channel, the swamps readily reestablished themselves, and more peat was formed. This cycle of peat formation and burial is responsible for the multiple seams of coal. The production of a 1-foot-thick seam of coal requires a 10-foot-thick deposit of peat; so the amount of wood in the Carboniferous forests must have been immense in order to produce the hundreds of feet of coal present in Pennsylvania.

In addition to trees and ferns, an increasingly diverse population of animals developed during Carboniferous time. Amphibians, primitive reptiles, air-breathing molluscs, and insects began to live in the many new habitats created by the diverse land plants.

*Environments of coal deposition*
*Cretaceous rocks, which are present in small areas of southern Montgomery County, cannot be shown at the scale of this map.
THE PERMIAN PERIOD

The Permian Period, which started about 299 million years ago, was a time of dramatic change caused by the collision of North America with Africa. The collision resulted in a mountain-building episode called the Alleghanian orogeny, which was of much greater magnitude in Pennsylvania than the earlier Taconic and Acadian orogenies. This collision caused deformation within the Appalachian basin. The stacking of thrust sheets in eastern North America raised a mountain range 150 miles wide, 750 miles long, and at least 2.5 miles high. The western margin of these Alleghanian mountains, which should not be confused with the present-day Allegheny Mountains, was located in the eastern part of Pennsylvania. Erosion of this mountain range yielded vast quantities of sediments that were carried westward to the Appalachian basin.

The Piedmont province (see centerfold map) today contains eroded remnants of some of the large sheets of rock that were thrust onto the eastern margin of the North American continent. Such thrust faulting also occurred in the subsurface rocks as far west as the Appalachian Plateaus province. Within the Ridge and Valley province, these nearly horizontal basal thrust faults commonly developed secondary splay faults that angled up toward the surface and caused upward bending of overlying rocks into folds called anticlines. The downward bends between the anticlines are called synclines. The orientation of the originally horizontal rocks was changed by various angles up to 90 degrees. The folding also squeezed the existing rocks in eastern Pennsylvania so that they covered a smaller area than before. For example, the rocks presently forming the crest of Blue Mountain between Harrisburg and Chambersburg were situated about 50 miles farther east prior to folding.

Fractures that formed during the collision became avenues for water infiltration. This promoted weathering and disintegration of the rock. The large quantity of sediments eroded from the Alleghanian mountains was deposited on an alluvial plain that covered much of Pennsylvania as well as areas farther west. Little is known about the character of the sediments because they have all been eroded except for a small amount in southwestern Pennsylvania and adjacent states.
By the end of the Permian Period, erosion had reduced the height of the mountain range in eastern Pennsylvania, and the remainder of Pennsylvania was mainly a westward-sloping alluvial plain across which streams flowed. The eroded tops of some anticlines probably protruded above the alluvial plain. This episode of deposition was the final one for the Appalachian basin. The Appalachian basin subsequently ceased to exist as an area of deposition.

During the Permian Period, Pennsylvania remained near the equator (as it was during the Carboniferous), but the climate became much drier. This happened because the plate movements that caused the Alleghanian orogeny involved all of the continents, which joined together to form a supercontinent called Pangea. There was limited rainfall in Pennsylvania because the state was near the middle of Pangea and no oceans were nearby. Thus, the swamps dried up, and the vegetation became less abundant and of a different type.

The formation of the supercontinent Pangea caused not only worldwide climate changes, but also worldwide changes in the ocean basins. In particular, the amount of shallow ocean water was greatly
reduced, because joining the continents together greatly reduced the continental-margin area. As a result, the end of the Permian is marked by the extinction of large numbers of marine organisms whose shallow-water environments were destroyed. Included among these organisms was the trilobite, whose numbers had been declining since the Devonian Period. However, while some marine environments were being destroyed, new land environments were being created, and animal life flourished there. Insects were prolific. The amphibians evolved, but were restricted in where they could live. They needed to remain close to water because it was the initial habitat for their eggs. During the Permian Period, the reptiles evolved and solved the egg problem by producing an egg with a hard shell, which permitted it to be laid on dry land. This allowed the reptiles to roam wherever they wanted, and soon they would dominate the animal world.

Supercontinent Pangea at the end of the Permian
THE MESOZOIC ERA

The Alleghanian orogeny changed Pennsylvania completely. It changed from a depositional basin receiving sediment to an area above sea level that has been eroded continuously ever since and is still supplying sediments to places outside the state. This long period of erosion, which started at least 250 million years ago, has produced the landscape that we see today. Most of the erosion was accomplished during the Mesozoic Era.

The three periods of the Mesozoic Era, the Triassic, Jurassic, and Cretaceous Periods, were approximately 51, 54, and 80 million years long, respectively. During the Triassic Period, the gradual northward movement of North America carried Pennsylvania across the equator into the northern hemisphere. The climate was subtropical to tropical. Rainfall was seasonal, and much of the year was very dry. In addition to annual wet and dry cycles, long-term wet and dry cycles occurred over tens of thousands of years. The long-term cycles are believed to be related to fluctuations in the amount of solar energy received. Erosion was probably intense at times, and much sediment was carried west or northwest away from Pennsylvania.

Sometime in the Late Triassic, possibly about 220 million years ago, the area where Africa and North America were joined together gradually began to separate. Convection currents in the mantle forced the continents apart and created new rock on the ocean floor that developed between them. This process is called seafloor spreading. As the separation of the continents took place, long, fault-bounded troughs, called rift basins, formed parallel to the margins of the con-
tinents. One of these rift basins is in southeastern Pennsylvania. All of the basins became sites for the deposition of sediments eroded from adjacent areas. During the wet part of the long climatic cycles, these basins were the sites of large lakes in which sediments were deposited. During the dry part of the cycles, the lakes dried up.

The process of seafloor spreading also caused deep-seated magma to approach the surface very early in the Jurassic Period. The magma cooled near the surface as diabase, a dark, hard igneous rock. In Pennsylvania, the Mesozoic sediments and diabase (shown in bright green and red on the centerfold map) are preserved in the Gettysburg-Newark basin of the Piedmont province.
While all of this was happening, the area between North America and Africa widened to become the Atlantic Ocean. The Atlantic is still widening today by about 2 inches per year. Near its center, at the Mid-Atlantic Ridge, magma continues to be brought to the surface, filling the available space between the separating plates with new rock.

Little is known about the Jurassic and Cretaceous Periods in Pennsylvania except that erosion occurred. Sometime, possibly during the Cretaceous but maybe earlier, rivers eroding the eastern part of the state began to flow to the east into the newly formed Atlantic Ocean, and the early stage of modern drainage was established. These rivers were very short initially, but gradually became longer through a process of headward erosion which continues today. In this process, the length of a stream is extended by erosion at its source, or head, area. Often during this process, the head of one stream will intersect another stream and capture a part of that stream by a process called stream piracy.

As the Atlantic Ocean became larger and ocean currents were established, the ocean provided a nearby source of water. This caused the climate to become wetter, and the amount of vegetation increased. During the Late Cretaceous, vegetation was sufficiently abundant to cause the accumulation of some peat in the southeastern part of the state. Physical weathering (the mechanical breakup of rock) and erosion of clastic sediments slowed down considerably during the latter part of the Cretaceous Period. By the end of the Mesozoic Era, chemical weathering (the alteration of the chemical composition of minerals at the earth’s surface) was dominant in Pennsylvania.

During the Mesozoic Era, the land was ruled by the dinosaurs, which flourished and evolved into many different types. Many other animals also existed. These included mammals and the first birds, both of which first appeared in the Late Triassic. Many of these land dwellers, as well as a variety of ocean dwellers, became extinct within a period of about a million years at the end of the Mesozoic Era. The extinction may be explained by the impact of a large asteroid. Such an impact would have created a large cloud of dust around the world that blocked sunlight and severely affected life. The presence of a large impact site at Chicxulub, Mexico, and debris from this impact at the boundary between Cretaceous and Tertiary sediments at many places around the world support this theory.
THE CENOZOIC ERA

The Cenozoic Era, which started approximately 66 million years ago, is divided into the Tertiary Period (about 66 to 1.8 million years ago) and the Quaternary Period (about 1.8 million years ago to the present). The Cenozoic Era is commonly discussed in terms of shorter subdivisions of time called epochs. During the Cenozoic Era, North America continued its northward motion to its present position relative to the equator.

The warm and moist climate of the Cretaceous Period continued into the early part of the Cenozoic Era and apparently intensified. This resulted in much chemical weathering, by which solid rock was converted to materials such as clays. This process led to the development of thick zones of very weathered clay-rich rock called saprolite. The actual appearance of Pennsylvania probably changed very little during this period of many million years, but solid rock was nowhere close to the surface by the time the process ended.

During the Miocene Epoch, which started about 23 million years ago, the climate began to change slowly to somewhat cooler and drier conditions. This caused an increase in physical weathering and erosion of clastic sediments and a decrease in chemical weathering. A time of severe erosion started about 16 million years ago during the Miocene and has continued to the present. It was during this time that the landscape that we see today was sculpted. Parts, if not all, of the land surface in eastern Pennsylvania may have been lowered by several hundred feet. At the same time, the dif-
ference in elevation between the highest and lowest points was increased considerably. The system of rivers, creeks, and rivulets that drain water from Pennsylvania today was established during this time of erosion, which was also a time of continued cooling.

About 1.8 million years ago, during the Pleistocene Epoch, large quantities of ice accumulated in Canada and formed continental glaciers that began to advance into Pennsylvania. The ice covered only a small part of the northern half of the state, mainly in the Appalachian Plateaus province.

In the glaciated areas, the advancing ice eroded and significantly deepened valleys that were parallel to the direction of ice flow. The ice also scraped and lowered the tops of hills, particularly in places where the underlying rock was a soft shale or siltstone. When the ice finally started to melt, it left behind deposits such as till, a mixture of clay, silt, sand, and gravel scattered randomly across the land surface, and outwash, stream-deposited sand and gravel that filled the bottoms of valleys leading away from the glacier.

This climate was very cold and caused the ground in most of Pennsylvania to be frozen to depths of several feet. In the area beyond
the limits of continental ice cover, numerous cycles of freezing and thawing occurred in the periglacial climate. The repeated freezing and thawing at the surface caused the breakup of large quantities of rock at the crests of ridges in the Ridge and Valley province. As a result, the crests of these ridges were lowered by several tens of feet. Loose rock, called talus, accumulated on the slopes of most ridges of central Pennsylvania and can be seen today in many places, such as the Juniata Narrows south of Lewistown.

At least three glaciers entered Pennsylvania at different times during the Pleistocene Epoch. Each successive glacier eroded deposits left by the earlier glaciers. Deposits of the earlier glaciers generally survived only where the earlier glaciers traveled farther south than their successors. The first of the glaciers arrived in Pennsylvania more than 800,000 years ago. The most recent arrived about 24,000 years ago. Between each glaciation, the climate became similar to that of today, or even warmer and wetter. It is possible that we are presently in an interglacial period and that sometime in the future glaciers will again grow in Canada and move southward to Pennsylvania.

Life on the land underwent many changes during the approximately 66 million years of the Cenozoic Era. Of particular significance was the appearance of grasses. The development of grass created a new food supply that was rapidly utilized by mammals, such as horses. The mammal population expanded and diversified to become the dominant class of animals on earth. Among these mammals were humans, who appeared very late in the Cenozoic.
PENNSYLVANIA’S PHYSIOGRAPHIC PROVINCES

The present-day landscape of Pennsylvania reflects the billions of years of events that have been described in this booklet. The events that took place in various parts of the state were different, and the landscape reflects those differences. Because of this, the state is divided into six areas called physiographic provinces, each of which has a particular type of landscape and geology. The physiographic provinces are labeled on the map in the center of this booklet.

The state’s southeasternmost physiographic province, the Atlantic Coastal Plain, includes all of Philadelphia except the northwestern part. It also includes the southeastern parts of Bucks and Delaware Counties. Beyond Pennsylvania, this province encompasses areas near the Atlantic Ocean from Massachusetts to Florida, including all of southern New Jersey and most of Delaware. It is marked by rather flat land and sandy soil. It contains sediments of Cenozoic age that are the result of erosion and deposition by rivers.

Moving inland, the first province that covers a large area within Pennsylvania is the Piedmont. From northwest Philadelphia, it extends north past Quakertown and west past Gettysburg. West Chester, Quarryville, Lancaster, and York are in this province. Metamorphic rocks that are at least 444 million years old underlie much of the Piedmont and have been greatly distorted by the forces of plate collisions. Following the Alleghanian orogeny, this was an area of grand mountain ranges. After millions of years of erosion, rolling hills are the only remnants of that early grandeur.

The part of the Piedmont that is shown in bright green and red on the map contains rocks that were formed during the beginning of the separation of North America and Africa. These rocks formed from the Late Triassic through the earliest Jurassic, about 200 million years ago. The landscape is one of rolling lowlands composed mainly of red sedimentary rock punctuated by hills of diabase, a hard igneous rock. Quakertown, Elizabethtown, and Gettysburg are in this part of the Piedmont province.

The part of the New England province in Pennsylvania, known as the Reading Prong, contains some metamorphic rocks that are about 500 million years old and many others that are more than a billion years old. These rocks are resistant to erosion, and the province is a
highland characterized by rounded hills. From Reading’s Mount Penn, the Reading Prong extends northeastward to Connecticut. It forms hills to the south of Allentown and Bethlehem. A small, isolated segment lies to the west of Reading.

The Ridge and Valley province contains one of Pennsylvania’s most distinctive landscapes. Geology students all over the nation study its unusual long, narrow, nearly parallel ridges and valleys, and they puzzle over the formation of water gaps that allow rivers to pass through the ridges. The province makes a broad sweep through the center of the state, extending northeastward into New Jersey and southwestward into Maryland and beyond. Altoona, Harrisburg, Williamsport, and Scranton are in this province. Most of the ridges and valleys consist of Paleozoic sedimentary rock. Some metamorphosed late Proterozoic volcanic rock that is about 575 million years old forms minor ridges in the South Mountain section of the province. The tremendous pressures that operated on the rocks of the Ridge and Valley province during the Alleghanian orogeny have left them folded and standing at angles far from the horizontal position in which the sediments were
originally deposited. Erosion since that time has formed valleys in areas of soft rock, such as shale and limestone, that alternate with ridges of harder rock, such as sandstone.

The province that covers the greatest area of Pennsylvania is the Appalachian Plateaus province. It extends from Greene and Somerset Counties in the southwest to Erie County in the northwest and to Wayne and Pike Counties in the northeast. Pittsburgh, Johnstown, Bradford, and Towanda are in this province. As in the Ridge and Valley province, the rocks are of Paleozoic age, but they were not affected as much by the mountain-building processes. This province is a highland that has been eroded by streams that have created deep valleys and hilly topography. Northern sections that were overridden by the glaciers of the Pleistocene Epoch also have lakes, swamps, peat bogs, and extensive deposits of loose sediments.

The northwesternmost province in Pennsylvania is the Central Lowlands province along the shore of Lake Erie in Erie County. Like the Atlantic Coastal Plain, this is a large province, only a small part of which is found in our state. From northwestern Pennsylvania and western New York, the province extends northwestward to Minnesota and southwestward to central Texas. The portion in Pennsylvania, which includes Erie, North East, and Girard, consists of gently rolling land. It contains low ridges of sand and gravel that are old beaches formed by Lake Erie at the end of the Pleistocene glaciation. At that time, the water level in the lake was much higher than it is now because the lake’s outlet, the Niagara River, was blocked by the receding glacier.
GEOLOGY’S PRACTICAL SIDE

The settlement of Pennsylvania was affected by geology. The high, wall-like, parallel ridges of the Ridge and Valley province, sometimes called the Endless Mountains, presented a barrier that limited most British colonial settlement in Pennsylvania to areas east of the mountains. The French had easier access to western Pennsylvania from Québec via the natural transportation routes of the Great Lakes and the Allegheny River. Later, people in eastern Pennsylvania who were attracted to the frontier chose to follow the easy transportation route that the wide, relatively flat Great Valley section provided southwestward into Virginia, where it is known as the Shenandoah Valley. Many settlers who finally did reach western Pennsylvania came from western Virginia (now West Virginia) by following the rivers northward. Pennsylvania’s geological setting has made the linking of the eastern and western parts of the state a challenge. The most successful links were the Pennsylvania Railroad in the 1800’s and the Pennsylvania Turnpike in 1940, which overcame the problem by tunneling through the mountains.

The effects of geology on settlement and transportation show us one aspect of geology’s practical side. Its effects are not limited to transportation, and many are to our benefit. It is easy to forget that, one way or another, water, food, and the raw materials to make everything we use come from the ground.

Long ago, deposits of raw materials were found by chance. Today, we cannot depend on chance to feed our tremendous appetite for these materials. By studying the earth’s history, we can rule out the least likely places to find what we need and concentrate on the places where we are more likely to have success. One important tool that helps us do this is the principle called “uniformitarianism,” which states that the geological processes that we see operating today are the same as those that took place in the past. Using that principle and combining it with their knowledge of stratigraphy, or the order and distribution
of rock units, that has been gained through generations of study, geologists can predict where resources might be found.

Pennsylvania’s geological history has left a legacy of many important resources. Coal formed from buried Pennsylvanian-age swamp vegetation is burned to generate electricity and to make iron and steel. Deposits of oil and natural gas, which are formed mainly from decayed organisms, are common in Silurian and Devonian rocks in the western part of the state. Oil and gas are used in the manufacture of fuels and lubricants. Coal, oil, and natural gas are also important raw materials in the manufacture of plastics, synthetic fabrics, fertilizers, pesticides, pharmaceuticals, and asphalt.

Pennsylvania is also an important producer of many nonfuel mineral resources. Sand and gravel, crushed sandstone, and crushed limestone are common construction aggregates, materials used to pave roads. Limestone, which has many other uses, is quarried in large quantities in Pennsylvania. It is used in construction as the cement required to make concrete, in agriculture to improve the soil chemistry for better plant growth, and in scrubbers that reduce air pollution from burning coal. Sandstone, slate, limestone, diabase, and other rocks are used as dimension stone, which is stone that is cut and sometimes polished for use in buildings and monuments. Clay is another important product of Pennsylvania’s mineral industry. It is used in the manufacture of bricks and ceramics, and as a sealer to protect water supplies from pollution caused by the disposal of hazardous waste. Clay and limestone are also used as fillers in the manufacture of foods, medicines, paper, and plastics.

The production of mineral resources in Pennsylvania can be traced to colonial times. Pennsylvania was once an important producer of metallic mineral resources. Iron, zinc, lead, chromium, and nickel from Pennsylvania helped fuel America’s development into an indus-
trial nation. Because of depletion and the discovery of deposits elsewhere that can be mined more economically, metallic resources are not presently mined in Pennsylvania. An iron mine at Cornwall in Lebanon County that helped supply the Continental Army during the Revolutionary War closed in the 1970’s after more than 230 years of operation. The last metallic mine, a large zinc mine in Lehigh County, closed in 1983.

Other resources continue to play an important role in Pennsylvania’s economy, and in providing what is needed to maintain our way of life. Pennsylvania is among the larger producers of nonfuel resources in the nation. The combined value of all of the geologic resources produced here in 2005 was approximately $5.3 billion.

Tourism has become one of Pennsylvania’s largest industries. Geology is an important aspect of many of the state’s tourist attractions. Outdoor enthusiasts are drawn to places like the Grand Canyon of Pennsylvania, Presque Isle, and Hickory Run Boulder Field. History buffs are attracted to sites such as the Gettysburg Battlefield, where the outcome of battle was partly shaped by such geologic features as Devils Den and Little Round Top. The Pennsylvania Anthracite Heritage Museum, the Cornwall Iron Furnace, and the Drake Well Museum are examples of tourist attractions that are directly related to Pennsylvania’s mineral resources. Even the difficulties posed in con-
necting the eastern and western parts of the state are recognized at
tourist attractions that honor the ingenuity that was employed in get-
ting people and goods across the mountains. Examples include the
Horseshoe Curve and the Allegheny Portage Railroad.

**SOMETIMES THINGS SEEM TO GO WRONG**

Because our planet seems to be a pleasant place to live and pro-
vides all that we need to survive, it is easy to think of Earth as well
adapted to our needs. This is especially true if we compare it to the
other planets in the solar system. Mercury is airless. Venus is a cloud-
shrouded oven that is hot enough to melt lead. The thin atmosphere
of Mars and its frigid temperatures, lack of water, and raging dust
storms make it less than ideal. The outer planets are balls of ice and
poisonous gases. We have to be careful about how we think of Earth,
though. Earth has not adapted itself to suit our needs. It is we, as a
result of millions of years of evolution, who have adapted ourselves
to live in the conditions that exist on Earth.

As pleasant as Earth may be, sometimes things seem to go wrong.
Floods, earthquakes, landslides, and sinkholes seem to come randomly
from nowhere and disrupt our lives. People wonder how such appar-
ently bad things could happen. They happen because the geologic
processes that change and renew the surface of the earth have not
stopped. These processes are neither good nor bad. They happen
naturally and often predictably. If we understand the processes, we
can sometimes avoid their bad effects.

By studying geology, we can learn which processes are likely to
present hazards in a particular area and how we can sometimes pre-
vent damage before it occurs. In Pennsylvania, with its extensive river
systems, floods cause great damage. Maps that show the elevation of
the ground can be combined with accounts of past floods to provide
an indication of where floods will occur in the future. In those areas,
precautions can be taken to reduce flood damage. The most obvious
precaution is to avoid building in those areas. The preservation of
wetlands, which absorb floodwaters, minimizes the impact of flood-
ing on built-up areas. Another precaution is to construct buildings in
such a way that a flood would cause as little damage as possible, for example, placing the things that would suffer the greatest damage on upper floors. Some communities attempt to reduce flood damage by building dikes or levees that redirect floodwaters.

Great earthquakes occur most often at plate boundaries in the Mediterranean region, southern Asia, and lands bordering the Pacific Ocean. Pennsylvania, which is far from a plate boundary, so far has had only small earthquakes over the 300 years since the first European settlers began to keep records. These earthquakes have caused little damage. Damage by major earthquakes can be reduced by use of construction techniques that isolate buildings from the violent motions of the ground, similar to the way shock absorbers allow cars to ride smoothly on bumpy roads.

Landslides have caused much more damage in Pennsylvania than earthquakes. There are several kinds of landslides. Some act very slowly over a period of years. The only evidence of movement might be something subtle, such as a misaligned fence. At the other extreme, a mass of soil and rock can suddenly and rapidly careen down a hillside, knocking down trees as it goes. In a third type of landslide, called a slump, a block of soil or weathered rock on a hillside slowly slides down and rotates outward as the weight of the material at the top of the block pushes down on the material at the bottom.
Much of the damage caused by landslides can be prevented by carefully studying the soil type, the slope, the presence and angle of fractures in the bedrock, and other factors before construction is begun. Sometimes, inappropriate construction can actually increase the risk of landslides. The danger can be reduced by taking precautions in preparing the site for construction.

Subsidence also causes problems in Pennsylvania. The usual cause of the ground caving in is the removal of bedrock. Bedrock can be removed by mining or, as unlikely as it might seem, by being dissolved. Groundwater that is slightly acidic slowly dissolves limestone, leaving an open space. Almost all well-known caverns formed in this way. If the rock remaining above the space is too weak to support the load above it, the ground collapses and a sinkhole forms. Careful study before construction is begun, especially in areas of limestone bedrock and old mine workings, can help prevent damage.
A CHANGING ENVIRONMENT

Environmental change is as old as the earth, itself. Since life arose, many things have changed, including the composition of the atmosphere, the amount of sunlight that reaches the ground, even the length of a day. Some of these changes were caused by the emergence of life. For example, when green plants first arose in the Proterozoic Eon, they gradually removed some of the carbon dioxide from the atmosphere and replaced it with oxygen. Life has adapted to such changes slowly by evolution. In each generation, every individual is slightly different from all others. The individuals that are best suited to their surrounding conditions survive to reproduce and carry on their line. As conditions slowly change, individuals having slightly different characteristics become the ones that are best suited to the new conditions and are the ones that reproduce. It is through this process of natural selection that one species gradually evolves into another.

Regardless of our level of technology, we change the earth by our presence, just as the Proterozoic plants changed the composition of the atmosphere by their presence. To some extent, probably every plant and animal has done this. Some scientists believe that changes taking place now may be occurring more rapidly than many of the changes that have taken place in the past. Conditions that developed over thousands or millions of years may be changing in decades. For example, a relatively rapid retreat of glaciers in North America, Europe, and the Antarctic, and a slight increase in sea level were observed in the closing years of the twentieth century. Natural selection cannot cope with such rapid changes. We face a challenge in determining whether the changes that have been observed represent a long-term trend of rapid change. If so, we face the additional challenge of trying to slow them and to adjust to those that cannot be slowed.

In addition to the effects of possible climate change, there are other ways in which we might be modifying our environment too rapidly. One is by changing the quality of the world’s water. For many years, people have dumped their refuse into bodies of water without considering the consequences. Today, we know that components of trash and sewage that are not disposed of properly can find their way into groundwater and streams and contaminate water supplies hundreds of miles away.
Most of Pennsylvania is an upland from which water flows via four major drainage systems through or past 15 other states, the District of Columbia, and two provinces of Canada before reaching the Atlantic Ocean and the Gulf of Mexico. Water from much of the interior of Pennsylvania flows down the Susquehanna River into Chesapeake Bay, which also receives water from a small area of south-central Pennsylvania through tributaries of the Potomac River. Delaware Bay receives water from many industrial areas of eastern Pennsylvania that line the Delaware, Lehigh, and Schuylkill Rivers. Most water from western Pennsylvania flows into the Allegheny and Monongahela Rivers, which meet at Pittsburgh to form the Ohio River. At Cairo, Ill., the Ohio River discharges into the Mississippi River, which carries Pennsylvania's water to Louisiana and the Gulf of Mexico. Water from the
lakeshore region of Erie County and from part of Potter County drains into the Great Lakes, then follows the St. Lawrence River through eastern Canada. Rivers also bring water into Pennsylvania from adjacent states. Lake Erie brings water to our shore from streams as far away as Minnesota.

It is now common to carefully plan trash-disposal sites and line them using clays and other materials as barriers to water movement. The barriers can help prevent pollution from entering water supplies. We no longer think of the earth’s resources as infinite. The ocean once seemed so huge that nothing could possibly pollute it. Today, we know that some pollutants stay around for a long time and build up until their effects can no longer be overlooked, even in the ocean. Awareness of this, and of the natural systems that govern everything on the earth, is making us think more about what we are doing and how we might do it better.

In these pages, we have journeyed through time from the Big Bang and the origins of the universe to the present. We have seen a dramatic sequence of events that has led to the development of modern-day Pennsylvania. We have also seen the importance of understanding this geologic history so that we can locate raw materials. Understanding the geologic framework allows us to reduce damage to property by predicting where geologic hazards might occur, and it allows us to avoid the mistakes of the past and to better protect the environment.

There are few aspects of life that are not dependent on geology. Nearly every object, every building, every vehicle, every appliance, is made from raw materials that come from the ground. Even food and raw materials such as cotton, wool, and wood are affected by geology because of the dependence of plants and animals on nutrients from the soil. Energy is stored in the ground in the form of oil, gas, uranium, and coal. The use of geothermal energy, using the heat of the earth’s interior, is becoming more common. Without water, our most precious resource, life itself would not be possible.

Today, we are faced with possibly our greatest environmental challenge, climate change. Whether the warming that has been observed is a result of natural processes, manmade carbon dioxide emissions, or a combination of the two, the result may be a significant sea-level
rise, shifting climate zones, storms, or the migration of plant and animal species.

Despite our best efforts, we cannot live on earth and use its resources without changing it. Our challenge is to keep the changes as small as possible. Adopting alternative energy sources combined with other measures, such as capturing carbon dioxide and storing it underground, may help us to meet that important challenge.

**ACKNOWLEDGMENTS**

The authors gratefully acknowledge the thoughtful reviews of this manuscript by Karen Evans, homemaker, Camp Hill, Pa.; Richard A. Gilman, geology professor (retired), State University of New York College at Fredonia; Richard C. Keen, librarian, Pennsylvania Geological Survey; and Richard A. Martin, earth science teacher, Mechanicsburg High School, Mechanicsburg, Pa. The encouragement and helpful suggestions of Donald M. Hoskins, Samuel W. Berkheiser, Jr., Jon D. Inners, Rodger T. Faill, and Robert C. Smith, II, of the Pennsylvania Geological Survey, are also appreciated.
